Abstract

High-resolution ultrasound has been used as an important tool in the diagnosis, management and monitoring of both acute and chronic peripheral nerve injuries. According to literature, it demonstrated high sensitivity and specificity for the detection of specific pathologies and its ability to differentiate between them. Literature has been reviewed, summarizing the specific finding of such modality in various peripheral neuropathies and with a specific focus over its role in evaluation and management of traumatic peripheral neuropathies.

Keywords: Ultrasonography; Evaluation; Management; Peripheral nervous system.

Introduction

Peripheral nervous system injuries can result in multiple pathologies, with involvement of single or multiple nerve units and subsequent sensory and/or motor impairment. Certain biological mechanisms were involved in injuries recovery such as axonal regeneration and/or re-myelination with resultant re-innervation of the targeted organ. This review aim to discuss the various peripheral neuropathies with a main focus on traumatic peripheral nerve injuries elaborating the different applications of ultrasound imaging in relation to the management and clinical assessment of such injuries.

Peripheral Neuropathies: Types and Classification

Etiologies of peripheral neuropathy ranges from acute, chronic to congenital anomalies; including various systemic illnesses and idiopathic pathologies. Trauma is one of the most common causes of acute peripheral neuropathy.

In a study involving 5,777 trauma patients, Noble et al. showed a 3% prevalence of traumatic peripheral nerve injuries that involved either upper and/or lower extremities; in which 54% required surgical intervention. Similarly in a retrospective study by Taylor et al, an incidence of 2% for traumatic nerve injuries in either upper or lower extremities was reported with the highest rate of such pathologies associated with crush injuries. A study by Seddon led to clinical identification and classification of such injuries into a three graded system (neurapraxia, axonotmesis and neurotmesis). This was later adapted into a five grade system by Sunderland, and recently has been updated to include a sixth grade; a combination of any of the five degrees of injury can be present together.

Findings of High Resolution Ultrasound Imaging In Various Peripheral Neuropathies

The concept of utilizing ultrasonography to evaluate peripheral nerves dates back to Solbiati et al; in which they evaluated this modality to assess the recurrent laryngeal nerve and to diagnose its associated palsy, particularly in cases of infiltrating thyroid or parathyroid pathologies. Focused imaging of the nerves, which is suspected to be involved and subsequent identification of the changes in their structure or lack of continuity, has helped in selecting the most appropriate management strategy and thereby has associated with improved outcome.

The study conducted by Fornage et al. helped in the differentiation between normal versus pathological conditions of peripheral nerves. The normal appearance of the nerves (Fig. 1) was shown to have echogenic fibrillar exterior texture; whereas, the pathological conditions ranged from masses to inflammatory conditions and was linked to a hypo-echoic with distal sound enhancement as well as thickening of the nerve. Silvestri, et al. utilized the same concept and found that in the peripheral nerves examined, hypo-echoic areas were separated by hyper-echoic bands. On histological examination, they showed that the hypo-echoic areas corresponded to the neuronal fascicles. This pattern was essential to differentiate the nerves from the surrounding tendons.

Further analysis of the sonographic imaging has aided better delineation of the peripheral nerves, demonstrating that the echogenic appearance of peripheral nerves lies between that of the corresponding muscle and tendon with muscles having more hypo-echoic appearance relative to peripheral nerves. This evolved to the identification of the echogenic exterior texture in longitudinal...
sections parallel to the axis of the nerve, whereas, cross sections produce a more reticular appearance.\textsuperscript{15}

Figure 1: Cross-sectional sonographic view of normal femoral nerve showing hyperechoic echo texture with few intraneural fascicles and associated hypoechoic background.

On the other hand, Nerve enlargement has been shown to occur at an early stage of several neuropathies, suggesting a potential application of ultrasound in early diagnosis.\textsuperscript{23} A study by Beekman R et al. found that nerve enlargement at multiple sites extended to the median, ulnar, radial and brachial plexus in patients with multifocal motor neuropathy.\textsuperscript{24} Furthermore, such findings were not accompanied by any electro-physiological or clinical abnormalities.\textsuperscript{25}

High-resolution sonography has been demonstrated to delineate the precise location, type and extent of post-operative complication such as hematoma or collection, in addition to enable assessment of the disease status of adjacent tissues surrounding the nerve.\textsuperscript{26}

High-resolution sonography has also been shown to have utility for the evaluation of brachial plexus pathology.\textsuperscript{27} In a study of 28 patients by Graif et al., ultrasound was able to detect abnormalities in 20 patients, which the cause of these pathological changes was trauma, benign and malignant primary tumors as well as secondary tumors; or nerve injury following irradiation therapy.\textsuperscript{27}

The use of ultrasound as a diagnostic modality has aided the field of surgical intervention directed towards peripheral nerves. In particular, it has demonstrated utility for confirming and/or excluding the presence of such injury when suspected.28,29 Their work showed that the use of ultrasound have aided the exclusion of any presence of nerve injuries when other modalities of diagnosis, for example clinical, electro-physiological and/or radiological diagnoses, have failed to do so (Table. 1). Other efforts showed the essential role of high-resolution ultrasound when used intra-operatively to localize the site (intraneural and/or perineural), type, and extent of nervous injuries making the operative intervention goal oriented with less invasive and time exploration and surgical identification of nervous tissue was evaluated well. Work of Lee FC, et al. have demonstrated the beneficial role of such modality in the intraoperative detection and localization of various surgical pathologies like neuromas or nerve entrapment following surgical ligation of surrounding nervous structures.28 Their work showed that the use of ultrasound have aided the exclusion of any presence of nerve injuries when other modalities of diagnosis, for example clinical, electro-physiological and/or radiological diagnoses, have failed to do so (Table. 1). Other efforts showed the essential role of high-resolution ultrasound when used intra-operatively to localize the site (intraneural and/or perineural), type, and extent of nervous injuries making the operative intervention goal oriented with less invasive and time...
Ultrasound is an effective tool for routine examination of peripheral nerve disorders and complemented neurophysiological assessment. This imaging modality has been successfully applied for the diagnosis of the formation of traumatic neuromas, which are non-neoplastic masses of proliferating cells that include fibroblasts, neurons and Schwann cells. Traumatic neuromas may develop because of surgical procedure or trauma (e.g: Motor vehicle accident, fall, etc.). The concept, that ultrasound could be the method of choice for diagnosing traumatic neuromas, was illustrated by a case report of a traumatic neuroma in an adult woman who received median nerve and associated tendon repair following a suicide attempt. Although electro-diagnostic testing was normal, ultrasonographic imaging demonstrated a hypo-echoic, focal swelling close to the median nerve that was consistent with the presence of a neuroma. Furthermore, a report of an ultrasound examination of accessory nerve lesions due to trauma in four cases, showed the feasibility of using this technique for the detection of pathological changes in the nerve following surgical procedures.

In addition, Ultrasound was able to diagnose traumatic peripheral neuropathies from penetrating or non-penetrating causes in both the upper and lower limbs. Likewise, ultrasound examination for peripheral neuropathy of the upper limb, which caused clinically diagnosed sensory or motor deficieny, showed a number of diagnostic features including loss of nerve continuity, axonal swelling together with a hypo-echoic nerve, presence of a neuronal stump, and partial nerve severance with an absence of the normal fasiccular nerve pattern; wherein surgical exploration had confirmed these diagnoses. The power of ultrasound imaging to diagnose traumatic neuromas is high where commonly the ultrasound show that the nerve distal to the neuroma is enlarged.

In cases of fine needle aspiration biopsy, ultrasound was able to detect traumatic neuromas in the neck in the absence of any clinical signs of neuromas. It also detected an iso-echoic mass with an internal hyper-echogenic lesion, which had a heterogeneous parallel pattern. A retrospective analysis of 24 pediatric cases with closed upper limb injuries following bone fractures and subsequent development of peripheral nerve motor and sensory palsy, reviewed the application of ultrasound in eight of these patients. Ultrasound revealed a 50% laceration of a radial nerve in one patient and radial nerves, which were constricted and buried in fracture callus, in two other patients. Based on these sonographic findings, these three patients underwent surgery that confirmed the ultrasound diagnoses. On the basis of ultrasound assessment, a conservative management plan was followed in the other five patients. The nerves in these patients were shown to be intact; although nerves were swollen, kinked close to the fracture site, or adjacent to an orthopaedic metal screw or wire, which impaired their function. Recovery of nerve function following surgery or conservative management was observed after around 12 weeks.

In a study by Filippou et al, high-resolution ultrasonography was found to be more useful than nerve conduction studies in localizing ulnar neuropathy, whether localized at the elbow, outside the elbow or due to previous trauma. There was a good correlation between ultrasonic measurement of the cross sectional area of the ulnar nerve at the sulcus and distal nerve conduction study results. A recent review of clinical trials addressing the application of ultrasonography in ulnar neuropathy at the elbow concluded that an increased cross sectional area of the ulnar nerve at the elbow was the most reliable parameter that was diagnostic of an abnormality.

In other literatures, this modality was compared to other imaging techniques, where the benefits of ultrasound over MRI were shown in the diagnosis of entrapment of the radial nerve following fracture of humerus.

This led to meticulous evaluation of high-resolution ultrasound together with other modalities, especially magnetic resonance imaging, in the evaluation of peripheral nerves in cases of trauma or any suspected pathology.

**Conclusion**

This article showed ultrasound as an extremely important tool in the diagnosis, management and monitoring of both acute and chronic peripheral nerve injury. Numerous studies in different indications have now demonstrated high sensitivity and specificity for the detection of specific pathologies and the ability to differentiate between them. Therefore, ultrasound represents a powerful tool in enabling appropriate planning for treatment, preventing unnecessary surgery where conservative management is sufficient and thus improving overall outcomes in patients with peripheral neuropathy.
